26 **Abstract**

27 Samples of waste cathode ray tube (CRT) plastic housings were exposed to Milli-Q® water
28 containing dissolved humic matter at concentrations of 0, 100 and 1000 mg L⁻¹ as leaching
29 fluid under laboratory conditions, and polybrominated diphenyl ethers (PBDEs) determined
30 in the resulting leachate. Despite the relatively hydrophobic physicochemical properties of
31 PBDEs, concentrations of ΣPBDEs in the leachate from the leaching experiments in this study
32 ranged from 14,000 – 200,000 ng L⁻¹. PBDE leaching appears to be a second order process,
33 whereby a period of initially intense dissolution of more labile PBDEs is followed by a slower
34 stage corresponding to external diffusion of the soluble residue in the material. The bulk of
35 transfer of PBDEs to the leaching fluid occurs within the first 6 hours of contact, during
36 which time we suggest that the most labile PBDEs are “washed” off the surface of the CRT
37 plastics. The predominant congeners in the chips were BDE-209 (2,600 mg kg⁻¹) and BDE 183
38 (220 mg kg⁻¹). The impacts on PBDE leaching of leachate pH and temperature were also
39 examined. Increasing the temperature of leaching fluids from 20 to 80 °C, enhances the
40 leachability of BDE-209 and BDE-99 from plastics. In all cases, the alkaline pH 8.5 examined,
41 resulted in the greatest PBDE concentrations in leachate. Agitation of the waste/leachate
42 mixture enhances PBDE leaching from CRT plastics. Potential evidence for debromination of
43 heavy congeners to the lower brominated and more bioavailable BDEs was observed.
44 Specifically, BDEs-47, -85 and -100 were detected in the leachates, but were absent from
45 the CRT plastics themselves.

1. Introduction

Polybrominated diphenyl ethers (PBDEs) are organic chemicals that historically were added to a plethora of consumer goods and materials such as electrical and electronic equipment (EEE) and textiles to impart flame retardancy. Total historic production of PBDEs (including Deca-BDE) has been estimated to amount to 1.3 million to 1.5 million tonnes between 1970 and 2005 (UNEP, 2010a). Three commercial mixtures exist: Penta-BDE, Octa-BDE and Deca-BDE (marker congeners for each are: BDEs 47 & 99; BDE-183; and BDE-209, respectively). North America contributed 97.5 % of global Penta-BDE production (8,290 tonnes), 35.9 % of Octa-BDE (1,375 tonnes), and 44.3 % of Deca-BDE (24,300 tonnes) (Hale et al., 2003). In contrast, Asia contributed 53 % of global Octa-BDE production (2,030 tonnes) and 42 % of Deca-BDE (23,038 tonnes), but manufactured no Penta-BDE (Hale et al., 2003). Europe accounted for the remaining global production of 2.5 % Penta-BDE (213 tonnes), 12 % Octa-BDE (460 tonnes) and 13.7 % Deca-BDE (7,515 tonnes) (Hale et al., 2003). In 1999, it was reported that North America accounted for 50.6 % of total PBDE consumption.

CRT housings were conventionally produced using either acrylonitrile butadiene styrene (ABS) copolymers or high impact polystyrene (HIPS). Historically, around 95 % of Octa-BDE supplied in the EU was used in ABS (globally ~70 %), to which it was typically added at concentrations between 10-18 % by weight (EC, 2011). The main uses for BFR-treated ABS were predominantly in housings of EEE, particularly for cathode ray tube (CRT) housings (e.g. PC monitors and TVs), and office equipment (e.g. copying machines and business printers). The remaining ~5 % of minor uses of Octa-BDE were in HIPS, polybutylene terephthalate (PBT), and polyamide polymers, with typical concentrations between 12-15 % by weight (EC, 2011). Other possible uses were in: nylon, low density polyethylene, polycarbonate, phenolformaldehyde resins, and unsaturated polyesters, as well as in adhesives and coatings (UNEP, 2010a; 2010b).

While ABS was predominantly treated with Octa-BDE, HIPS was mainly treated with Deca-BDE typically added at concentrations between 13-15 % by weight (EC, 2011; BSEF, 2014). Widely used due to its relatively low cost, Deca-BDE was employed in a range of plastics/polymers and textiles. In plastics, Deca-BDE was used for EEE housings, in the

81 automotive and aeronautic sectors and in construction, in applications such as wires and
82 cables, pipes and carpets (BSEF, 2014).

83 Despite their extensive use, acute toxicity studies have suggested that PBDEs can be
84 hepatotoxic at relatively high doses (Zhou et al., 2002; Bruchajzer et al., 2011). Moreover,
85 several studies have indicated that Penta- and Octa-BDE mixtures, as well as several of the
86 major individual congeners present in wildlife and people, can alter liver enzymes, disrupt
87 thyroid homeostasis, and are associated with early onset of puberty, reduced fertility, and
88 impaired neurological development (Viberg et al., 2007). In general, the lower brominated
89 congeners are more acutely toxic than the higher ones (Darnerud, 2003). Consistent with
90 this, are reports that decabromodiphenyl ether (BDE-209) displays low acute toxicity when
91 given by the oral, inhalation and dermal route (Kelly et al., 2008; Tomy et al., 2008; Wu et
92 al., 2009). Moreover, some studies report that BDE-209 does not appear to be genotoxic, is
93 not teratogenic, and does not seem to cause developmental toxicity (Hardy et al., 2009;
94 Wang et al., 2010). In contrast however, work by Johansson et al., (2008) suggests that BDE-
95 209 can be as potent as the lower brominated PBDEs in causing developmental neurotoxic
96 defects.

97 Such evidence of toxicity is compounded by evidence that PBDEs are environmentally
98 ubiquitous (de Wit, 2002; Law et al., 2006; de Wit et al., 2006; Kohler et al., 2008; Harrad et
99 al., 2009). Concerns over the toxicology and persistence of these chemicals are exacerbated
100 by evidence of PBDEs inside the human body. Numerous studies have reported the
101 presence of PBDEs in human adipose tissue, blood serum, liver, placenta, cord blood and
102 breast milk worldwide (Noren and Meironyte, 2000; Choi et al., 2003; Petreas et al., 2003;
103 Covaci et al., 2008a; Toms et al. 2009). However, BDE-209 is considered relatively less
104 persistent and bioaccumulative than the lower brominated congeners. These concerns
105 about their adverse environmental impacts have meant that production of the Penta- and
106 Octa-BDE commercial mixtures ceased in the EU and North America in 2004, and their use in
107 all applications in 2006. Likewise, Deca-BDE was restricted severely in the EU in 2008. US
108 manufacturers voluntarily committed to phase it out from most uses in the USA by the end
109 of 2012, and ended all use by 31 December 2013 (BSEF, 2014).

As a further reflection of concern about their use, the Penta- and Octa-BDE commercial mixtures (tetra-, penta-, hexa- and hepta-BDEs) are listed as persistent organic pollutants (POPs) by the United Nations Environment Programme (UNEP) under the Stockholm Convention on POPs, while Deca-BDE is under active consideration for listing (UNEP, 2014).

Notwithstanding the bans and restrictions on manufacture of PBDEs, the reservoir of PBDEs present in waste EEE (WEEE) has and will continue to, gradually enter the waste stream, and there is hence a pressing need to understand the fate of chemicals like PBDEs associated with WEEE following disposal. While landfilling of WEEE is now restricted in many jurisdictions, in the early part of 21st century, Alcock et al. (2003) estimated that >80 % of total BFR-containing waste was landfilled in the UK and North America, leaving a substantial legacy. Potential emission pathways for chemicals associated with landfill include leaching and volatilisation. The physicochemical properties of PBDEs (Table 1), suggest following disposal to landfill, such leaching and volatilisation of PBDEs associated with treated WEEE may not be extensive. However, PBDEs have been reported in landfill leachate (Oliaei et al., 2002; Osako et al., 2004; Oliaei et al., 2010) and a study into PBDE leaching from WEEE demonstrated that PBDEs can be present in distilled water and landfill leachates at significant concentrations (Danon-Schaffer et al., 2013). This study conducts a series of controlled laboratory experiments to test the hypothesis that PBDEs are capable of leaching from waste CRT plastic housings. We further hypothesise that the leaching of PBDEs from the waste CRT plastic housings will be influenced by leachate temperature and pH, along with waste:leachate contact time and whether the waste is agitated during contact with the leachate.

2. Materials and methods

2.1. Samples and sample preparation.

The waste material studied in our experiments consisted of flame-retarded CRT plastic housings donated by Sims Recycling Solutions, UK. In 2013, a 1 kg grab sample of CRT housings taken from the PC and TV monitors waste plastic stream at a waste treatment plant was collected for this study. The CRT plastics had been subjected to a size reduction step at the waste treatment plant and were supplied as chips of ~ 5-25 mm diameter. The

chipped CRT plastic samples were manually separated from additional debris within the waste stream grab sample. Any wood, metal, or wires were removed prior to weighing.

2.2. Chemical analysis of initial PBDE concentrations in CRT plastics.

To assess the homogeneity of the starting material, five 30 mg aliquots of the homogenised plastic sample were analysed before conducting leaching experiments. PBDEs in hard plastic samples were extracted by means of a modified version of the combined ultrasound assisted extraction and vortexing method described by Ionas et al. (2012).

In order to improve the extraction, the hard plastics were subjected to a size reduction step to increase the contact surface area with the solvent. Due to the rigidity of the matrix and size of plastic chips obtained (approximately 2 mm × 5 mm × 5 mm) a Fritsch Pulverisette 0 cryo-vibratory micro mill (Idar-Oberstein, Germany) was employed for this purpose. The samples along with one 25 mm diameter stainless steel ball were added to the stainless steel grinding mortar (50 mL volume) and submerged in liquid nitrogen until they reached the temperature of the surrounding liquid (-196 °C). It was then ground at a vibrational frequency of 30 Hz for 10 min and repeated 3-4 times. The resulting plastic particles varied in size, but typically passed through a 250 µm mesh aluminium sieve pre-rinsed with acetone, toluene and *n*-hexane.

The extraction process for the resulting homogenised plastic particles consisted of consecutive steps of vortexing for 1 min and ultrasonication for 15 min with 10 mL of *n*-hexane in pre-cleaned test tubes. This cycle of vortexing and ultrasonication was repeated 3 times. The samples were left in solvent overnight to maximise recoveries. No destructive clean-up method was applied to minimise any degradation of PBDEs.

2.3. Leaching test methods

Three distinct experimental scenarios were undertaken to examine the effects on the leaching behaviour of PBDEs from CRT plastics: (a) plastic-leachate contact time, (b) leachate temperature, and (c) pH level of the leaching fluid. All scenarios employed single batch experiments where the CRT plastics were contacted once only with the leaching fluid. In scenario (a) experiments, CRT plastic samples were exposed to the leaching fluid for

either 6 h, 24 h or 48 h. Both scenarios (a) and (c) were conducted at the prevailing room temperature (20 °C). In scenario (b) experiments examining the influence of temperature of the leaching fluid on leaching behaviour, experiments were conducted in which CRT plastics were contacted with leaching fluid for 24 h at three different temperatures (20, 50, and 80 °C). Finally, in scenario (c) experiments examining the influence of pH of the leaching fluid on leaching behaviour; experiments were conducted in which CRT plastics were contacted with leaching fluid for 6 h at three different pH levels (acidic 5.8, slightly acidic 6.5, and alkaline 8.5). In both scenarios (a) and (c), contact vessels were agitated at 200 rpm. In all three experiment scenarios, dissolved humic matter (DHM) solutions of 0 mg L⁻¹, 100 mg L⁻¹ and 1000 mg L⁻¹ were employed as leaching fluids. Conditions employed in these experiments are summarised in Supplementary Information (SI).

Polytetrafluoroethylene (PTFE) bottles (500 mL) were used as contact vessels during controlled leaching experiments. The whole volume of the contact vessel was not completely filled with leaching fluid and as a result a headspace was present inside the contact vessel. In all experiments on CRT plastics, 5 g of sample was contacted with 125 mL of Type 1 ultrapure Milli-Q® water giving a liquid-solid ratio of 25:1 (v/w). Following addition of the sample and leaching fluid, contact vessels were horizontally agitated on a mechanical shaker at 200 rpm for the desired contact time. The exception was for experiments examining the influence of temperature, which were not agitated and instead were maintained at the desired temperature for 24 h by immersion of the contact vessel in a thermostatically controlled water bath. Each of the above leaching experiments were conducted in duplicate.

Leaching fluids were prepared using Milli-Q® water. The pH levels were determined before each experiment using a pH meter (Hanna, USA) and levels were corrected using either glacial acetic acid (Sigma-Aldrich) or sodium hydroxide (Sigma-Aldrich) solutions. In scenarios (a), (b) and (c), DHM solution was prepared by dissolving Aldrich humic acid (sodium salt) in Milli-Q® water. The solution was stirred for 5 minutes until total dissolution and then the pH was adjusted to the desired level, before finally it was centrifuged at 2000 rpm for 1 min.

2.4. Chemical analysis of leachates

After contacting the leaching fluid, the leachate obtained from each of the different experimental conditions was filtered through a 0.45 μm pore size glass fibre filter (Advantec, Japan) to remove any small particles or fibres of the flame retarded material and then spiked with 50 ng each of $^{13}\text{C}_{12}$ -labelled BDE-47, -99, -153 and -209, as internal (or surrogate) standards. The collected filtrate was then extracted in series using 3 x 50 mL dichloromethane by liquid-liquid extraction with mechanical shaking for 10 minutes each time. Approximately 5-10 mL 2 % NaCl solution was added post-experiment to leachates containing no DHM to enhance separation after extraction. When the NaCl solution was used on DHM containing leachates it produced an undesirable emulsion between the interface of the two layers and reduced PBDE recovery efficiencies. The combined dichloromethane extracts were dried via filtration through 5 g anhydrous Na_2SO_4 .

The dried extract was concentrated to 0.5 mL using a Zymark Turbovap II (Hopkinton, MA, USA) with solvent exchange to *n*-hexane before elution through a pre-cleaned acidified silica (1 g of 44% concentrated sulfuric acid, w/w) and Na_2SO_4 column with 30 mL of *n*-hexane:DCM (9:1 v/v). The eluate was concentrated with solvent exchange to *n*-hexane before evaporation to incipient dryness, addition of $^{13}\text{C}_{12}$ -labelled BDE-100 as recovery determination (or syringe) standard and dilution in methanol prior to analysis via LC-MS/MS equipped with an Atmospheric Pressure Photoionization source (APPI).

An additional extraction step was performed on the glass fibre filters used in the filtrate. After filtration of the leachate, filters were desiccated in a silica gel-containing glass desiccator covered with aluminium foil to prevent any potential photo-degradation of PBDEs. Any visible particles of plastic retained on the filters were carefully removed with tweezers prior to extraction. Filters were then extracted via five cycles of vortexing and ultrasonication. The individual filters for each experiment and 5 mL of a positive azeotropic mixture of *n*-hexane:acetone (3:2 v/v) were added to a pre-washed test tube, vortexed for 1 min and sonicated for 5 mins. The supernatant was transferred to a clean tube, the extraction was repeated and both supernatants were combined (10 mL total) and vortexed for 1 min. The filter extract was then cleaned up in identical fashion to the leachate extracts.

2.5 Determination of concentrations of PBDEs

Concentrations of BDEs-47, -85, -99, -100, -153, -154, -183, and -209 in all samples generated from leaching experiments and pulverised homogenised plastics samples were quantified using a dual pump Shimadzu LC-20AB Prominence high pressure liquid chromatograph (Shimadzu, Kyoto, Japan) equipped with a Sciex API 2000 triple quadrupole mass spectrometer (Applied Biosystems, Foster City, CA, USA) (see SI for additional details).

2.6. Calculation of PBDE leaching

The percentage of PBDEs leached from the CRT plastic housing chips into each leachate sample (PL) was calculated as in equation 1:

$$\text{Equation 1: } PL = \left[\frac{C_{leachate} \times V}{C_{waste} \times W} \right] \times 100\%$$

PL = percentage leached (%)

$C_{leachate}$ = Conc. of PBDEs collected in leachate (mg/L)

V = volume of leachate (L)

C_{waste} = Conc. of PBDEs in waste sample (mg/kg)

W = total weight of waste sample (kg)

The percentage leached normalised to contact time (PLT , % h⁻¹) is expressed here as the percentage of PBDEs leached from the CRT plastic chips per hour of contact time. PLT is calculated according to equation 2.

$$\text{Equation 2: } PLT = \frac{PL}{t}$$

PL = percentage leached (%)

t = contact time (h)

3. Results and discussion

3.1. Initial PBDE concentrations in CRT plastic samples

Table 1 displays the mean initial concentrations and aqueous solubilities of individual PBDE congeners in the CRT plastics used in this study. Concentrations of BDE-47, BDE-85 and BDE-100 were below their respective limits of quantification (LOQs): 217 ng g⁻¹, 13 ng g⁻¹ and 12 ng g⁻¹.

Deca-BDE was the predominant congener found in the samples followed by Octa-BDE. This may be due to HIPS being more prevalent in the grab sample of CRT chips, or because Deca-BDE, to some extent, replaced Octa-BDE in ABS plastics after the EU ban on Octa-BDE (Lassen et al., 2006). Concentrations of ΣPBDE are <1 % by weight suggesting that some dilution has occurred, indicating that some plastic chips within the CRT waste stream sample were likely not treated with PBDEs. It is likely that some of the chips were treated with Deca-BDE, a smaller fraction with Octa-BDE and some did not contain PBDEs. This is supported by the fact that hand-held XRF analysis of these chips revealed a heterogeneous distribution of Br (pers. comm., Antonella Guzzonato, University of Birmingham, 2014). Further to this, according to Wäger et al., (2011), tetrabromobisphenol A (TBBPA) is the predominant BFR found in CRT monitors collected from Swiss WEEE recycling sites and it was also suggested by the authors that TBBPA was applied in ABS plastics.

3.2. Effects of contact time and humic matter content of leaching fluid on PBDE leaching (single batch experiments).

The liquid-solid ratio, contact durations and agitation speed were selected during method development after reviewing established standardised leaching protocols from North America, Europe and Japan and conducting initial experiments. Concentrations of DHM solutions used in experiments were 0 mg L⁻¹, 100 mg L⁻¹ and 1000 mg L⁻¹. Landfill site leachates can contain a wide spectrum of dissolved organic matter concentrations, usually in the range between ~100 mg L⁻¹ up to ~50,000 mg L⁻¹ (Kjeldsen et al., 2002).

Table 2 presents PBDE congener concentrations in duplicate samples, as well as mean PL (%) and mean PLT values (% h⁻¹) in leachate from the single batch contact time experiments.

Relatively little change in PBDE concentrations in leachate are observed with increasing contact time for leaching fluids containing 0 and 100 mg L⁻¹ DHM. This suggests that the bulk of the transfer to the leaching fluid is occurring within the first 6 hours, during which time the most easily available PBDEs are “washed” off the surface of the CRT plastics. Therefore, serial batch experiments were not considered. However, the concentrations of ΣPBDEs in the leachate did increase slightly with longer contact times in the presence of the 1000 mg L⁻¹ DHM leaching fluid.

Contacting the CRT plastics with Milli-Q® water alone as the leaching fluid resulted in surprisingly high PBDE concentrations when considering the hydrophobicity of the higher brominated congeners (Table 1). We therefore suggest that dislodgement of fine dust from the surface of the CRT plastics was an important leaching mechanism for the more hydrophobic BDEs-153, -154, -183 and -209. Any dust that was present on the surface of the chips may be “washed” off when the leaching fluid was added to the chamber. If PBDEs had partitioned into this dust they would be more readily leached. These results are somewhat similar to those reported by Danon-Schaffer et al., 2013. An alternative mechanism would be abrasion of the CRT chips during agitation of the leaching chamber resulting in ultrafine particles of the flame retarded plastics being present in the leachate.

Aqueous solubility is likely to be more important for the relatively more soluble lower brominated PBDE congeners. These more soluble congeners are more readily dissolved in the aqueous leachate resulting in higher PLT values than observed for the higher brominated PBDEs. While BDE-47, BDE-85 and BDE-100 were not present at substantial concentrations in the CRT chips, they were detected in some of the leaching fluids, with the highest concentrations for these congeners in leachate detected in experiments with the longest contact times. This suggests either some debromination of the heavier PBDE congeners has occurred or reflects the relatively higher aqueous solubility of the lower brominated congeners. This is similar to our earlier work on hexabromocyclododecane (HBCDD; Stubbings et al., 2016), where ε-HBCDD was present in quantifiable concentrations in leachate after being contacted with HBCDD treated textiles, despite being <LOQ in the textile leached. These results are also to some extent similar to those reported by Danon-Schaffer et al., 2013.

312

313 3.3. Leaching kinetics

314 Ho et al., (2005) expressed the leaching of water-soluble organic components from sapwood
315 in terms of a second-order rate equation and being somewhat analogous to the condition
316 for our experiments, this equation was then applied to the leaching of PBDEs from CRT
317 plastics as the following:

318 Equation 3:
$$\frac{Ct}{t} = k(Cs - Ct)^2,$$

319 where k is the second-order leaching rate constant ($L\ ng^{-1}\ min^{-1}$), C_s the leaching capacity,
320 which is the concentration of PBDEs at saturation ($ng\ L^{-1}$), and C_t is the concentration of
321 PBDEs ($ng\ L^{-1}$) in suspension at any given time, t (min). The leaching capacity, C_s , and the
322 second-order leaching rate constant, k , can be determined experimentally from the slope
323 and intercept by plotting t/C_t against t .

324 We generated plots of t/C_t against t for all single batch experiments ($n = 6$) conducted at 20
325 °C and agitated at 200 RPM. The slope, Y-intercept, saturated leaching capacity, C_s , the
326 leaching rate constant, k , two-tailed p values, and Pearson's correlation coefficients, r , are
327 given for individual PBDEs in Table 3. A positive and highly significant ($p < 0.05$) linear
328 correlation between t/C_t and t was observed for BDE-100 and BDE-209 with leaching fluids
329 at $0\ mg\ L^{-1}$ DHM (Milli-Q® water), while weaker correlations are observed for BDE-153 (90 %
330 probability), -154 (84 % probability) and -183 (91 % probability). At $100\ mg\ L^{-1}$ DHM only
331 BDE-154 shows a highly significant correlation, while BDE-153 (90 % probability) and BDE-
332 183 (82 % probability) show weaker correlations. With the $1000\ mg\ L^{-1}$ DHM leaching fluid,
333 BDE- 100, 153 and 183 are significantly correlated ($p < 0.05$) and BDE-209 shows a weaker
334 significance (93 % probability). Example plots of t/C_t versus t are provided for DHM
335 concentrations 0, 100 and $1000\ mg\ kg^{-1}$ in the SI (Fig. S2-4).

336 While the small sample size ($n=6$) is acknowledged, this apparent fit with second order
337 kinetics suggests initial rapid leaching followed by a slower second phase. This is consistent
338 with our hypothesis that the most readily available PBDEs are “washed” off the CRT polymer
339 surface early in the experiment. A second, slower stage follows, which corresponds

primarily to external diffusion and is related to the soluble remainder within the polymer matrix. This kinetics model seems especially relevant to the higher brominated PBDE congeners.

To further evaluate the hypothesis of second-order rate kinetics, the natural logarithms of the same PBDE leachate concentration data for single batch experiments conducted at 20 °C, were plotted against contact time to check for linearity and negative slope intercepts that would suggest first order kinetics. The results are presented as SI (Fig. S5). The only congener to satisfy all first-order criteria was BDE-99 when the leaching fluid contained 100 mg L⁻¹ DHM. A weaker correlation (92 % probability) was observed for BDE-100 at the same DHM concentration. This strongly supports the idea that leaching of PBDEs from CRT plastics in these experiments is predominantly governed by second-order leaching kinetics.

3.4. Effects of the temperature of leaching fluid on PBDE leaching from CRT plastics

Within a landfill, temperatures can sometimes reach as high as 80-90 °C due to heat released during aerobic degradation (Kjeldsen et al., 2002). Therefore, the influence on PBDE leaching from CRT plastics of leachate temperatures of 20 °C, 50 °C and 80 °C was investigated. The only other study the author is aware of examining the effects of leachate temperature on PBDE leaching only examined differences between temperatures of 10 °C, 20 °C and 25 °C (Danon-Schaffer et al., 2013).

Table 4 presents PBDE congener concentrations in duplicate experiments as well as mean PL (%) and mean PLT values (% h⁻¹) in leachate from single batch temperature experiments. The highest concentrations of PBDEs were observed when Milli-Q® water was used as leaching fluid and contacted at 50 °C and 80 °C. Potential reasons for this could be related to reduced PBDE extraction efficiencies from DHM solutions, or from the filters in which DHM had passed through. This result is different from the findings of analogous studies contacting WEEE plastics with deionised water by Danon-Schaffer et al., (2013) and Choi et al., (2009). In these studies, PBDE concentrations were always significantly higher in leachate/DHM solutions, than those detected when deionised water was the leaching fluid. We note that concentrations of PBDEs were consistently higher in the 1000 mg L⁻¹ DHM leaching fluid

when compared to the concentrations found in the 100 mg L⁻¹ DHM leaching fluid. This is addressed further in section 3.7.

No agitation was used in these temperature experiments and this resulted in lower overall concentrations of PBDEs when compared with the agitated contact time experiments at 20 °C. Because no agitation occurred in these temperature experiments it is very unlikely that abrasion of particles contributed to the concentrations of PBDEs in the leachate. BDE-85 was not detected in the leachates in these temperature experiments.

3.5. Effects of the pH of leaching fluid on PBDE leaching from CRT plastics.

The pH levels used were based on real measured leachate pH levels that with only very few exceptions, lie in the range 5.8 to 8.5 (Renou et al. 2008). The influence of three pH levels, representing an acidic leachate (5.8), an alkaline leachate (8.5) and a mildly acidic leachate (6.5) on PBDE concentrations in leachate, were explored. PBDE congener concentrations in duplicate samples, as well as mean PL (%) and mean *PLT* values (% h⁻¹) in leachate from these pH experiments are listed in Table 5.

There is very little variation in total PBDE concentrations in leachate at the different pH levels examined. Experiments with acidic pH (5.8) leaching fluids yield the lowest ΣPBDE concentrations of the three pH levels examined. The only other study of which we are aware that examined the influence of pH on PBDE leaching from WEEE (Danon-Schaffer et al., 2013) reported that acidic leaching fluids of pH 4-5 facilitated a greater leaching of PBDEs than those of pH 7 and 9, and that the enhancement of leaching at acidic pH was more marked for less brominated PBDEs.

3.6. Effects of agitation on PBDE leaching from CRT plastics.

By comparing the results of experiments conducted at 20 °C with contact times of 24 h in the agitated contact time experiment and the non-agitated experiment conducted at the same temperature and contact time, the effect of agitation on leaching of PBDEs from the CRT plastics can be examined (Figure 1).

The Σ PBDE concentrations in the agitated experiments were 178 % greater than in the equivalent non-agitated experiments at 0 mg L⁻¹ DHM, 353 % greater at 100 mg L⁻¹ DHM and 124 % greater at 1000 mg L⁻¹ DHM. This illustrates that agitation has a considerable role in enhancing PBDE leaching from CRT plastics. The results of paired samples t-tests are presented in the SI (Table S5). There are highly significant differences ($p < 0.05$) between BDE-153, BDE-183 and BDE-209 concentrations in the leachate generated in agitated and non-agitated experiments and a weaker significant difference observed for BDE-100 (90 % probability).

3.7. Effects of DHM concentration of leaching fluid on PBDE leaching from CRT plastics

It has been reported that the presence of DHM in leaching fluids enhances the leachability of PBDEs suspended in water (Choi et al., 2009). However, there are multiple instances in this study in which leachates from experiments containing no DHM have higher concentrations and *PLT* values (% h⁻¹) than leachates containing DHM.

PBDE concentrations, mean PL (%) and mean *PLT* values (% h⁻¹) in leachate from those experiments examining leaching at different pH and at DHM concentrations of 0, 100, and 1,000 mg L⁻¹ are illustrated in Table 5.

3.8 Statistical analysis of the whole data set

A multiple linear regression analysis (MLRA) was performed for the entire data set for each PBDE congener. Leachate concentrations were used as the dependent variable, while DHM concentration, temperature, contact time, pH and whether the samples were agitated or not were used as independent variables. The independent variables for each PBDE congener are ranked by relative importance and significance and presented as SI (Table S6). The coefficients for each significant independent variable are also presented and can be used to predict how much the dependent variable is expected to increase when that independent variable increases by one, holding all the other independent variables constant.

However, we acknowledge that a degree of uncertainty is involved in performing an MLRA on the dataset due to the low number of data points compared to the number of influencing

variables. Additionally, the PBDE concentrations in the starting material likely vary between each experiment.

The effect of the length of contact time on BDE-209 concentrations was highly significant ($p < 0.05$). The coefficients predict that BDE-209 concentrations increase by 720 ng L⁻¹ for each additional hour of contact with the leaching fluid.

The effect of contact time also has a highly significant positive effect on leachate concentrations of the lower brominated congeners BDE-47 and BDE-85. They are more soluble and relatively hydrophilic than the heavier congeners so one would expect them to leach relatively quickly if they were present in the plastics to start with. A possible alternative explanation may be that external diffusion of these congeners is a slow process that requires greater than 24 h contact time.

Interestingly, the effect of agitation on PBDE leaching was highly significant and led to enhanced concentrations of BDEs -153, -100, -99, -85, and -47. This supports the hypothesis of a PBDE “wash off” effect.

The pH of the leaching fluid has a highly significant positive effect on the leaching of BDEs -154, -100, -99, -85, and -47. The largest effect was observed for BDE-154. In all cases, the alkaline 8.5 pH elicited the greatest concentrations.

The effect of the presence of DHM in the leachate elicits a significant positive effect on BDE-99 and BDE-100 leachate concentrations. However, this effect is ranked as least important when predicting the influence of the independent variables.

4. Summary

This study shows that substantial concentrations of PBDEs can be leached under laboratory conditions from CRT waste despite the low aqueous solubility of the higher brominated PBDEs. Concentrations observed here in leachate for Σ PBDEs (14,000 – 200,000 ng L⁻¹) are comparable to those reported in raw leachates from landfill (Öman and Junestedt, 2008; Odusanya et al., 2009; Kwan et al., 2013) and are 48 to 680 times higher than the highest reported BDE-209 concentration in a river system (295 ng L⁻¹) (Cristale et al., 2013). Our data

suggests that leaching of the higher brominated PBDEs from CRT plastics using Milli-Q® water as a leaching fluid is a second order process. Following an initial period of source:leaching fluid contact during which leaching is relatively facile, subsequent leaching is slower. This is perhaps not the case for lower brominated congeners BDE-47, BDE-85, and BDE-99 for which the kinetic process is less obvious due to low concentrations in the leachate and may potentially be formed by debromination.

Although attempts were made to ensure each 5 g aliquot of CRT plastic chips were representative of the bulk chipped sample, the heterogeneous mixture of the CRT plastics perhaps has a confounding effect on trends. It is likely that not all plastic chips present in the bulk sample used were flame retarded with PBDEs, while some were treated with Octa-BDE and others with Deca-BDE. Therefore, the starting concentrations of PBDE congeners in the different 5 g aliquot of the CRT plastic chips used in each leaching experiment may have been variable. Additionally, variability in the morphology of the CRT plastic chips such as the thickness, surface area, porosity and/or strength of the of the plastic may have influenced the potential for PBDEs to partition into the leaching fluid resulting in different leaching rates from chip to chip (Brandsma et al., 2013a).

These caveats aside, it appears that increasing the temperature of leaching fluids from 20 to 80 °C, enhances the leachability of BDE-209 and BDE-99 from plastics. There is also some potential evidence for debromination of heavy congeners to the lower brominated and more bioavailable BDEs. Specifically, this relates to the detection of BDEs-47, -85 and -100 in the leachates, despite their absence from the CRT plastics themselves. This has implications for the potential for PBDEs to migrate into surface and ground waters due to the preferential physicochemical properties of lower brominated PBDEs.

Agitation of the sample during leaching has a significant impact on PBDE concentrations in the leaching fluid despite the issue of the inhomogeneity of the starting material. This perhaps suggests that the other factors evaluated are unlikely to exert a similarly strong influence on leaching of PBDEs, otherwise we would be able to detect it as we can for agitation.

The data presented here are preliminary and there are few comparable studies in the literature (Danon-Schaffer et al., 2013; Choi et al., 2009). Further work is required to fill

knowledge gaps and develop a greater understanding of PBDE leaching behaviour from WEEE polymers and other PBDE treated materials.
